Memory corruption

**Buffer overflow** is a common vulnerability.

- Simple cause:
  - putting $m$ bytes into a buffer of size $n$, for $m > n$
  - corrupts the surrounding memory

- Simple fix:
  - check size of data before/when writing

Overflow *exploits*, where corruption performs something specific the attacker wants, can be very complex.

We’ll study simple examples to explain how devastating overflows can be, starting with simple **stack overflows** and **heap overflows**.

Examples will use Linux/x86 to demonstrate; principles are similar on other OSes/architectures.

Memory
Corrupting stack variables

Local variables are put close together on the stack.

- If a stray write goes beyond the size of one variable
- ... it can corrupt another
Application scenario

```c
int authenticate(char *username, char *password) {
    int authenticated; // flag, non-zero if authenticated
    char buffer[1024]; // buffer for username

    authenticated = verify_password(username, password);

    if (authenticated == 0) {
        sprintf(buffer,
                "Incorrect password for user %s\n",
                username);
        log("%s",buffer);
    }
    return authenticated;
}
```

- Vulnerability in `authenticate()` call to `sprintf()`. If the username is longer than 995 bytes, data will be written past the end of the buffer.
Possible stack frame before exploit

password: 0x080B8888
username: 0x080B4444
saved EIP (return addr)
saved EBP (frame ptr)
authenticated: 0x00000000
(undefined contents)
buffer[1024]
(undefined contents)
buffer start addr
If username is >995 letters long, authenticated is corrupted and may be set to non-zero.

E.g., char 1024=‘\n’, the low byte becomes 10.
Local variable corruption remarks

Tricky in practice:

▶ location of variables may not be known
  ▶ memory addresses can vary between invocations
  ▶ C standards don’t specify stack layout
  ▶ compiler moves things around, optimises layout

▶ effect depends on behaviour of application code

A more predictable, general attack works by corrupting the fixed information in every stack frame: the frame pointer and return address.

Summary
The malicious argument overwrites all of the space allocated for the buffer, all the way to the return address location. The return address is altered to point back into the stack, somewhere before the attack code. Typically, the attack code executes a shell.
Attacker controlled execution

By over-writing the return address, the attacker may either:

1. set it to point to some known piece of the application code, or code inside a shared library, which achieves something useful, or
2. supply his/her own code somewhere in memory, which may do anything, and arrange to call that.

The second option is the most general and powerful.

How does it work?
Arbitrary code exploit

The attacker takes these steps:

1. store executable code somewhere in memory
2. use stack overflow to direct execution there
3. code does something useful to attacker

The attack code is known as **shellcode**. Typically, it launches a shell or network connection.

Shellcode is ideally:

- small and self-contained
- position independent
- free of ASCII NUL (0x00) characters

**Question.** Why?
Arbitrary code exploit

1. store executable code somewhere in memory
2. use stack overflow to re-direct execution there
3. **code does something useful to attacker**

Summary
Building shellcode

Consider spawning a shell in Unix. The code looks like this:

```c
#include <unistd.h>
...
char *args[] = { "/bin/sh", NULL }; execution("bin/sh", args, NULL)
```

- `execve()` is part of the Standard C Library, `libc`
- It starts a process with the given name and argument list and the environment as the third parameter.

We want to write (relocatable) assembly code which does the same thing: constructing the argument lists and then invoking the `execve` function.
Invoking system calls

To execute a library function, the code would need to find the location of the function.

- for a dynamically loaded library, this requires ensuring it is loaded into memory, negotiating with the linker
- this would need quite a bit of assembly code

It is easier to make a system call directly to the operating system.

- luckily, execve() is a library call which corresponds exactly to a system call.
Invoking system calls

Linux system calls (32 bit x86) operate like this:

- Store parameters in registers EBX, ECX, ...
- Put the desired system call number into AL
- Use the interrupt int 128 to trigger the call
Invoking a shell

Here is the assembly code for a simple system call invoking a shell:

```assembly
; data section
.args:
    .long arg        # char *[/bin/sh]
    .long 0
.arg:
    .string "/bin/sh"

.text
.globl main
main:
    movl $arg, %ebx
    movl $args, %ecx
    movl $0, %edx
    movl $0xb, %eax
    int $0x80    # execve("/bin/sh",[/bin/sh],NULL)
    ret
```
From assembly to shellcode

However, this is not yet quite shellcode: it contains hard-wired (absolute) addresses and a data section.

**Question.** How could you turn this into position independent code without separate data?
From assembly to shellcode

Moreover, we need to find the binary representation of the instructions (i.e., the compiled code).

This will be the *data* that we can then feed back into our attack.
$ gcc shellcode.s -o shellcode.out
$ objdump -d shellcode.out
...
080483ed <main>:
  80483ed:  bb a8 84 04 08  mov $0x80484a8,%ebx
  80483f2:  b9 a0 84 04 08  mov $0x80484a0,%ecx
  80483f7:  ba 00 00 00 00  mov $0x0,%edx
  80483fc:  b8 0b 00 00 00  mov $0xb,%eax
  8048401:  cd 80  int     $0x80
  8048403:  c3  ret

▶ We take the hex op code sequence bb  a8  84... etc and encode it as a string (or URL, filename, etc) to feed into the program as malicious input.

Redirecting execution

Heap overflows

Specific heap attacks

General heap attacks

Summary
Arbitrary code exploit

1. store executable code somewhere in memory
2. use stack overflow to direct execution there
3. code does something useful to attacker

Two options:

- shellcode on stack
- shellcode in another part of the program data

Problem in both cases is:

- how to find out where the code is?
The exact address of the attack code in the stack is hard to guess. The attacker can increase the chance of success by allowing a range of addresses to work. The overflow uses a \textit{NOP sled}, which the CPU execution "lands on", before being directed to the attack code.
Attack code elsewhere in memory

- password: 0x080B8888
- username: 0x080B4444
- saved EIP 0x0BADC0DE
- saved EBP 0x41414141
- authenticated: 0x41414141

- user-controlled data seeded with executable code

- Various (intricate) possibilities
- E.g., modifying function pointers or corrupting caller’s saved frame pointer

  Redirecting execution

Heap overflows
  Specific heap attacks
  General heap attacks

Summary
Heap overflows: overview

The **heap** is the region of memory that a program uses for dynamically allocated data.

The runtime or operating system provides *memory management* for the heap.

With *explicit* memory management, the programmer uses library functions to allocate and deallocate regions of memory.
Memory safety (reminder)

Memory safety
A programming language or analysis tool is said to enforce *memory safety* if it ensures that reads and writes stay within clearly defined memory areas, belonging to different parts of the program.
malloc(size) tries to allocate a space of size bytes.

- It returns a pointer to the allocated region
- ... of type void* which the programmer can cast to the desired pointer type
- or it fails and returns a NULL pointer
- The memory is uninitialised so should be written before being read from

**Question.** Which points above contribute to (memory) unsafe behaviour in C?
Memory allocation in C

`calloc(size)` behaves like `malloc(size)` but it also initialises the memory, clearing it to zeroes.

**Question.** Suppose we allocate a string buffer, and immediately assign the empty string to it. What security reason may there be to prefer `calloc()` over `malloc()`?
Memory allocation in C

`free(ptr)` frees the previously allocated space at `ptr`.

- No return value (void)
- If it fails (`ptr` a non-allocated value), what happens?
  - if `ptr` is NULL, nothing
  - “undefined” otherwise,
  - program may abort, or might carry on and let bad things happen
- What happens if `ptr` is dereferenced after being freed?
  - depends on behaviour of allocator

**Question.** Suppose we accidently call `free(ptr)` before the final dereference of `ptr()` but before another call to `malloc()`. Is that safe?

Heap overflows
  Specific heap attacks
  General heap attacks

Summary
Simple heap variable attack

Without memory safety, heap-allocated variables may overflow from one to another.

```c
char *user = (char *)malloc(sizeof(char)*8);
char *adminuser = (char *)malloc(sizeof(char)*8);

strcpy(adminuser, "root");

if (argc > 1)
    strcpy(user, argv[1]);
else
    strcpy(user, "guest");

/* Now we'll do ordinary operations as "user" and create sensitive system files as "adminuser" */
```

▶ Is it possible to overflow user and change adminuser?
Simple heap variable attack

**Problem**: how do we know where the allocations will be made?

- Heap allocator is free to allocate anywhere, not necessarily in adjacent memory

Let’s investigate what happens on Linux x86, glibc. (for a particular version, on a particular day, . . . )
Simple heap variable attack

```c
#include <stdlib.h>
#include <string.h>
#include <stdio.h>

void main(int argc, char *argv[]) {

    char *user = (char *)malloc(sizeof(char)*8);
    char *adminuser = (char *)malloc(sizeof(char)*8);

    strcpy(adminuser, "root");

    if (argc > 1)
        strcpy(user, argv[1]);
    else
        strcpy(user, "guest");

    printf("User is at %p, contains: %s\n", user, user);
    printf("Admin user is at %p, contains: %s\n", adminuser, adminuser);
}
```
$ gcc useradminuser.c -o useradminuser.out
$ ./useradminuser.out
User is at 0x9504008, contains: guest
Admin user is at 0x9504018, contains: root

$ ./useradminuser.out
User is at 0x9483008, contains: guest
Admin user is at 0x9483018, contains: root

$ ./useradminuser.out frank
User is at 0x8654008, contains: frank
Admin user is at 0x8654018, contains: root

- Buffers not adjacent, there’s some extra space
- Addresses not identical each run (next lecture...)
- But admin user is stored higher in memory!
Let’s try overflowing....

$ ./useradminuser.out frank........david
User is at 0x9405008, contains: frank........david
Admin user is at 0x9405018, contains: id
Let’s try overflowing....

$ ./useradminuser.out frank.......david
User is at 0x9405008, contains: frank.......david
Admin user is at 0x9405018, contains: id

Count more carefully:

$ ./useradminuser.out frank56789ABCDEFdavid
User is at 0x9f0b008, contains: frank56789ABCDEFdavid
Admin user is at 0x9f0b018, contains: david

Whoa!
Let’s try overflowing....

$ ./useradminuser.out frank........david
User is at 0x9405008, contains: frank........david
Admin user is at 0x9405018, contains: id

Count more carefully:

$ ./useradminuser.out frank56789ABCDEFdavid
User is at 0x9f0b008, contains: frank56789ABCDEFdavid
Admin user is at 0x9f0b018, contains: david

Whoa!

**Question.** Can you think of a way to prevent this attack?
Remarks about heap variable attack

- same kind of attack is possible for (mutable) global variables, which are allocated statically in another memory segment
- this is an application-specific attack, need to find security-critical path near overflowed variable
- need to be lucky: overwriting intervening memory might cause crashes later, before the program gets to use the intentionally corrupted data

Is there a more generic attack for the heap?
Outline

Stack variable corruption

Executable code exploits
   Shellcode
   Redirecting execution

Heap overflows
   Specific heap attacks
   General heap attacks

Summary
Heap allocator implementation

A common heap implementation is to use blocks laid out contiguously in memory, with a free list intermingled. Heap blocks have headers which give information such as:

- size of previous block
- size of this block
- flags, e.g., in-use flag
- if not in use, pointers to next/previous free block

The doubly-linked free list makes finding spare memory fast for the malloc() operation.
Heap allocator implementation

typedef struct mallocblock {
    struct mallocblock *next;
    struct mallocblock *prev;
    int prevsize;
    int thissize;
    int freeflag;
    // malloc space follows the header
} mallocblock_t;

- If freeflag is non-zero, the block is in the freelist
- Allocator will split blocks and coalesce them again
General heap overflow attack

Rough idea:

- Coalescing blocks unlinks them from the free list
- Attacker makes unlink() do an arbitrary write!
  - uses overflow to set next and previous
  - and set flags to indicate free
  - unlink() then performs write
Unlinking operation

```c
void unlink(mallocblock_t *element) {
    mallocblock_t *mynext = element->next;
    mallocblock_t *myprev = element->prev;

    mynext->prev = myprev;
    myprev->next = mynext;
}
```

- performs two (related) word writes
  - mynext->prev = *mynext+2, myprev->next = *myprev

- attacker arranges at least one of these to be useful

**Exercise.** Check you understand this: draw a picture of a doubly linked list and explain how the attacker can make an arbitrary write.
Writing to arbitrary locations

What locations might the attacker choose?

- **Global Offset Table (GOT)** used to link ELF-format binaries. Allows arbitrary locations to be called instead of a library call.
- **Exit handlers** used in Unix for return from `main()`.
- Lock pointers or exception handlers stored in the Windows *Process Environment Block* (PEB)
- Application-level function pointers (e.g. C++ virtual member tables).

The details are intricate, but library exploits and toolkits are available (e.g., Metasploit).
Heap spraying and browser exploits

Apart from operating system (C code) memory management, other application runtimes provide memory allocation features, which may be accessible to an attacker.

A particular case is in browser-based exploits which have made use of heaps for managed runtimes such as JavaScript, VBScript, Flash, HTML5.

Writing shell code to predictable heap locations is sometimes called heap spraying. This is simple in concept: string variables manipulated in scripts are allocated in a heap.

Summary
Review questions

Stack overflows

- Explain how uncontrolled memory writing can let an attacker corrupt the value of local variables.
- Explain how an attacker can exploit a stack overflow to execute arbitrary code.
- Draw an stack during a stack overflow attack with a NOP sled and shell code, giving addresses.

Heap overflows

- Describe the API functions used to interface to heap allocation in C. Give two examples of risky behaviour.
- Show how overflowing one heap-allocated variable can corrupt a second.
- Explain how a heap overflow attack can exploit memory allocation routines to allow arbitrary writes.
We’ll looking other kinds of overflow attacks, and the general protection mechanisms mentioned at the start.

The best way to understand these attacks is to try them out!

We will try out more examples in **Lab 2** next week.
